Universal Variable-to-Fixed Length Codes
Achieving Optimum Large Deviations Performance for
Empirical Compression Ratio

Tomohiko UYEMATSU, Member

1. Introduction

Comparisons between lossless variable-to-fixed (V-F) length codes and fixed-to-variable (F-V) length codes have been done by many researchers. Especially, Ziv [1] has shown that for Markovian sources with long memory there exists a V-F length code that provides a better compression ratio than any F-V length code with the same number of codewords. Tjalkens and Willems [2] have proved similar results for universal coding of binary memoryless sources. Finally, Merhav and Neuhoff [3] have shown that for universal sources the best V-F length code provides a better large deviations performance than any F-V length code with the same number of codewords. Especially, they have considered a random variable, referred to as the empirical compression ratio (ECR), which is defined as the length in bits of the encoder output word divided by the length in bits of the input word. It has been shown that the exponential decay rate of the probability that the ECR exceeds $R$, for the best V-F length code, is $1/R$ times faster than that of the best F-V length code with the same number of codewords.

In this paper, we clarify that for finite-state sources Lempel-Ziv (LZ) code [4] with fixed number of phrases achieves the optimum large deviations performance, more precisely, asymptotically minimizes the probability that the ECR exceeds $R$ among V-F length code with the same code length. Further, for unifilar sources, an adaptive version of arithmetic codes [5]-[8] with fixed code length also achieves the optimum large deviations performance.

Of related works, we mention the following two results. Teuhola and Raita [9] proposed a V-F code using an arithmetic coding, which was very similar to our proposed code. However, they were interested in the practical performance of the coding and did not investigate its asymptotic performance. Viswanarayeh and Kulkami [10] have proposed an universal V-F code for the class of Markovian sources which is asymptotically optimum. However, their criterion of optimality is not ECR but redundancy.

2. Optimum Code for Finite-State Sources

Let $x = x_1 x_2 \cdots x_i \cdots x_n$ be a sequence of observable random variables taking values in a finite alphabet $X$. Similarly, let $s = s_1 s_2 \cdots s_i \cdots s_n$ be another sequence of random variables, called states, which take values in another finite set $S$. A probabilistic source $P$ is called finite-state (with $|S|$ states) if

$$P(x, s) = \prod_{i=1}^{n} P(x_i, s_i | s_{i-1}),$$

where $P(x_i, s_i | s_{i-1})$ is the joint probability of a letter $x_i$ and a state $s_i$ given the previous state $s_{i-1}$. $P(x, s)$ is the joint probability of $a$ and $s$, and $a_0 \in S$ is a fixed initial state. The class of finite-state sources with no more than $S$ states will be denoted by $P_S$.

Let $X^*$ denote the set of all words over alphabet $X$. A set of words $Z \subset X^*$ is said to be prefix set. We require it to be proper and complete. Properness of the prefix set implies that no word in $Z$ is a prefix of any other word in $Z$. Completeness guarantees that each infinite sequence $x_{1}, x_{2}, \cdots$ has one and only one prefix that belongs to $Z$. Any prefix set $Z$ can be represented by a complete $|X|$-ary tree $T(Z)$, where $T(Z)$ has $Z$ as the set of terminal nodes (cf. e.g. [11]).

A V-F length code $f : X^* \to \{0, 1\}^n$ can be characterized by a prefix set $\{X_1, X_2, \cdots, X_N\} \subset X^*$ with $N(\leq 2^n)$, which can be represented by a complete $|X|$-ary tree $T_n$ with $N$ terminal nodes, and the one-to-one mapping from each prefix (or terminal node) $X_i$ ($i = 1, 2, \cdots, N$) to binary codeword of length $n$ bits. From the definition, it is obvious that every infinite word $X$ has one and only one prefix $X_i \in T_n$. In what
follows, for infinitely long sequence X, we shall adopt the notation \( \ell(X) \) as the length of the prefix of X in \( T_n \), namely \( \ell(X) \triangleq \ell(X_i) \) where \( X_i \) is the prefix of X in \( T_n \). Then, the empirical compression ratio (ECR) associated with a V-F length code \( f : X^n \to \{0,1\}^n \) and an infinite source sequence X is defined as

\[ p_f(X) \triangleq \frac{n}{\ell(X)}. \]

Given a finite-state source P and a constant \( R > 0 \), we consider a problem to find a V-F length code \( f : X^n \to \{0,1\}^n \) that minimizes the probability that the ECR exceeds \( R \), defined as

\[ \Pr(p_f(X) > R) \triangleq \sum_{x \in \mathcal{X} : \ell(x) > nR} P(x), \]

where \( P(x) = \sum_{s \in \mathcal{S}_x} P(x, s) \) and \( P(x, s) \) is in (1). It is assumed that \( H(P) < R < \log_2 |\mathcal{X}| \), where \( H(P) \) is the Shannon entropy, which for a stationary source is given by

\[ H(P) \triangleq -\lim_{n \to \infty} \frac{1}{n} \sum_{x \in \mathcal{X}^n} P(x) \log P(x). \]

Now, consider following V-F code which is a V-F version of the Lempel-Ziv code [4].

**LZ code with fixed codelength**

\( L_{\ell_z} : X^n \to \{0,1\}^{n_m} \)

1. (Initialize) Let \( m > 1 \) be an integer which specifies the codelength. Let \( x_1 x_2 \ldots x_i \) be an output sequence of the source. Then, let \( w(1) \leftarrow x_1, j \leftarrow 1 \) and \( i_j \leftarrow 1 \). Output \( x_1 \) in \( \lfloor \log_2 |\mathcal{X}| \rfloor \)-bit.

2. (Parsing) Suppose \( w(1) \cdots w(j) = x_1 \cdots x_i \).
   
   (i) If \( x_{i_j+1} \notin \{w(1), \ldots, w(j)\} \) then \( w(j+1) \leftarrow x_{i_j+1} \) and \( p \leftarrow 0 \).
   
   (ii) Otherwise, \( w(j+1) = x_{i_j+1} \cdots x_{k+1} \), where \( k \) is the least integer greater than \( i_j \) such that \( x_{i_j+1} \cdots x_{k+1} = w(p) \) for some \( 1 \leq p \leq j \) and \( x_{i_j+1} \cdots x_{k+1} \notin \{w(1), \ldots, w(j)\} \).

3. Output a pair \( \{p, x_{k+1}\} \) in \( \lfloor \log_2 (j+1)|\mathcal{X}| \rfloor \)-bit. If \( j < n \) then \( j \leftarrow j + 1, i_j \leftarrow k + 1 \) and go to 2.

Otherwise, terminate the algorithm.

The codelength of this code is given by

\[ n_m \triangleq \sum_{j=1}^{n_m} \lfloor \log_2 |\mathcal{X}| \rfloor. \]

The following theorem establishes the asymptotic optimality of the LZ code in the sense of minimum probability of the ECR exceeding \( R \).

**Theorem 1**: For every finite-state source \( P \in \mathcal{P}_S \), any V-F length code \( f : X^n \to \{0,1\}^{n_m} \) with ECR \( p_f(X) \), every \( R \in (H(P), \log_2 |\mathcal{X}|) \), and all large \( m \),

\[ \Pr(p_f(X) > R + \epsilon([n_m/R])) \leq (1 + \eta([n_m/R]))\Pr(p_f(X) > R), \]

where \( \rho_{LZ}(X) \) is the ECR of LZ code with a fixed codelength \( n_m \), \( \eta(n) = n^{2n^{-n} \sqrt{\log n}} \) and \( \epsilon(n) = O(1/\sqrt{\log n}) \) is a positive sequence depending on \( \mathcal{X} \) and \( \mathcal{S} \).

Theorem 1 states that the LZ code achieves the optimum ECR performance, i.e., the best large deviations performance.

Before the proof of Theorem 1, we introduce a proposition obtained by Merhav [12] which shows the dual result of ours. That is, LZ code yields the shortest length, uniformly for every sufficiently long sequence \( x \), among all information lossless F-V codes for any finite-state source.

**Proposition [12, Theorem 1]**: For any F-V length code, let \( L_n(x) \) denote the codelength for \( x \in \mathcal{X}^n \). Then, for every \( B \in (H(P), \log_2 |\mathcal{X}|) \), every finite-state source \( P \in \mathcal{P}_S \), and all large \( n \),

\[ \Pr\{x \in \mathcal{X}^n : n^{-1} U_{LZ}(x) > B + \epsilon(n)\} \leq (1 + \eta(n))\Pr\{x \in \mathcal{X}^n : n^{-1} L_n(x) > B\}, \]

where \( U_{LZ}(x) \) denote the codelength of LZ code (when used as F-V code) for a sequence \( x \in \mathcal{X}^n \), while \( \eta(n) \) and \( \epsilon(n) \) are given in Theorem 1.

**Proof of Theorem 1**: It is easy to see

\begin{align*}
\Pr(p_f(X) > R) &= \Pr\{x \in \mathcal{X}^{[n_m/R]} : U_{LZ}(x) > R[n_m/R]\} \\
&= \Pr\{x \in \mathcal{X}^{[n_m/R]} : ([n_m/R])^{-1} U_{LZ}(x) > R\}. \tag{2}
\end{align*}

On the other hand, let us consider any V-F length code \( f : X^n \to \{0,1\}^{n_m} \) with a complete prefix tree \( T_{n_m} \). By using the method introduced by Merhav and Neuhold [3, Proof of Theorem 2] (see also Appendix), we can construct a F-V code \( \tilde{C}_m \) with block length \([n_m/R] \) from a given V-F code \( f \) such that

\[ \Pr\{x \in T_n : \ell(x) < n_m/R\} \]

\[ = \Pr\{x \in \mathcal{X}^{[n_m/R]} : \tilde{L}(x) > n_m\} \]

where \( \tilde{L}(x) \) denotes a length of codeword in \( \tilde{C}_m \) corresponding to \( x \in \mathcal{X}^{[n_m/R]} \). Hence,

\[ \Pr(p_f(X) > R) \]

\[ = \Pr\{x \in \mathcal{T}_{n_m} : \ell(x) < n_m/R\} \]

\[ = \Pr\{x \in \mathcal{X}^{[n_m/R]} : \tilde{L}(x) > n_m\} \]

\[ \geq \Pr\{x \in \mathcal{X}^{[n_m/R]} : ([n_m/R])^{-1} \tilde{L}(x) > R\} \]

\[ \geq \frac{1}{1 + \eta([n_m/R])}\Pr\{x \in \mathcal{X}^{[n_m/R]} : ([n_m/R])^{-1} U_{LZ}(x) > R + \epsilon([n_m/R])\}, \]

where the last inequality comes from Proposition. Combining this and (2) yields the theorem.
3. Optimum Code for Unifilar Sources

In this section, we restricted our attention to a unifilar source with a finite alphabet \(X = \{1, 2, \cdots, M\}\) and a generic distribution \(P\). For unifilar sources, the state \(s_i\) at time instant \(i\) obeys the recursion
\[
s_i = \psi(s_i, s_{i-1}),
\]
where \(f: X \times S \to S\) is a known deterministic mapping. Further, we assume that the initial state \(s_0\) is fixed, and clearly we can reconstruct the state sequence \(s\) recursively by observing the output sequence \(\omega\). Hence, for a fixed initial state \(s_0\), the probability of a given source sequence \(\omega = x_1 x_2 \cdots x_n\) is given by
\[
P(\omega) = \prod_{i=1}^{n} P(x_i|s_{i-1}).
\]

For unifilar sources, Merhav and Neuhoff [3] have shown that the optimum V-F length code provides the exponential decay rate of the probability that the ECR exceeds \(R\). Combining this result and Theorem 1, we conclude that the LZ code with a fixed coderlength can universally achieve the optimum exponential decay rate as the coderlength tends to infinity. In what follows, we demonstrate that another simple V-F length code, namely, an adaptive arithmetic code with fixed coderlength can also achieve the optimum exponential decay rate.

First, we shall describe the encoding algorithm.

**Fundamental encoding algorithm \(f_n: X^n \to \{0, 1\}^n\)

1) (Initialize) Let \(X \leftarrow 0, Y \leftarrow 1, i \leftarrow 1, s \leftarrow s_0, u(s) \leftarrow M (\forall s \in S)\) and \(F_j(s) = j (j = 0, 1, \cdots, M)\), \(\forall s \in S\).

2) (Encoding of the \(i\)th symbol) When \(x_i = k\), set
\[
X \leftarrow X + Y \ast F_{k-1}(s)/u(s),
Y \leftarrow Y \ast (F_k(s) - F_{k-1}(s))/u(s),
L \leftarrow [-\log_2 Y + \log_2 (i + M)].
\]
If \(L \leq n\) then go to step 3). Otherwise find an \(n\)-bit binary fraction \(z\) such that \(z \in [X, X + Y)\), and output \(z\), and terminate the algorithm.

3) Set \(F_j(s) \leftarrow F_j(s) + 1 (j = k, k+1, \cdots, M)\) and \(u(s) \leftarrow u(s) + 1\). Then, set \(s \leftarrow \psi(x_i, s)\) and \(i \leftarrow i + 1\). Go to step 2). \(\square\)

Next we shall describe the decoding algorithm.

**Fundamental decoding algorithm \(\varphi_n: \{0, 1\}^n \to X^n\)

1) (Initialize) Let \(X \leftarrow 0, Y \leftarrow 1, i \leftarrow 1, s \leftarrow s_0, u(s) \leftarrow M (\forall s \in S)\) and \(F_j(s) = j (j = 0, 1, \cdots, M)\), \(\forall s \in S\). Further, let \(Z\) be the \(n\)-bit fractional number corresponding to the codeword.

2) (Decoding of the \(i\)th symbol) Find an index \(k \in \{1, 2, \cdots, M\}\) such that \(X + Y \ast F_{k-1}(s)/u(s) \leq Z < X + Y \ast F_k(s)/u(s)\), and output \(k\) as the \(i\)th symbol. Set
\[
X \leftarrow X + Y \ast F_{k-1}(s)/u(s),
Y \leftarrow Y \ast (F_k(s) - F_{k-1}(s))/u(s),
L \leftarrow [-\log_2 Y + \log_2 (i + M)].
\]
If \(L \leq n\) then go to step 3). Otherwise terminate the algorithm.

3) Set \(F_j(s) \leftarrow F_j(s) + 1 (j = k, k+1, \cdots, M)\) and \(u(s) \leftarrow u(s) + 1\). Then, set \(s \leftarrow \psi(x_i, s)\) and \(i \leftarrow i + 1\). Go to step 2). \(\square\)

**Remark 1:** The above algorithm is an adaptive arithmetic coding using Laplace's law of succession (see e.g. [13], [14]) for the estimation of the generic distribution \(P\) of the unifilar source. It should be noted that the variable \(L\) is introduced in order to check if the next input symbol can be encoded into the same codeword.

Next theorem shows the asymptotic performance of the proposed codes.

**Theorem 2:** The probability that the ECR of the proposed code \(f_n: X^n \to \{0, 1\}^n\) exceeds \(R\) satisfies
\[
\liminf_{n \to \infty} \left[-\frac{1}{n} \log_2 \Pr(\rho_{f_n}(X) > R)\right] \geq \frac{1}{R} \min_{Q: H(Q) \geq R} D(Q || P) ,
\]
where the minimum is taken over all probability mass functions \(Q\) over \(X \times S\), and
\[
H(Q) \triangleq -\sum_{i \in S} \sum_{x \in X} Q(x, s) \log_2 Q(x|s),
\]
\[
D(Q || P) \triangleq \sum_{i \in S} \sum_{x \in X} Q(x, s) \log_2 \frac{Q(x|s)}{P(x|s)},
\]
with \(Q(x|s) = Q(x, s)/\sum_{i \in S} Q(x, s)\).

Merhav and Neuhoff [3] have shown that any sequence \(\{f_n\}\) of V-F length code \(f_n\) with \(2^n\) codewords satisfies
\[
\limsup_{n \to \infty} \left[-\frac{1}{n} \log_2 \Pr(\rho_{f_n}(X) > R)\right] \leq \frac{1}{R} \min_{Q: H(Q) \geq R} D(Q || P).
\]

Hence, the proposed code can universally achieve the optimum exponential decay rate, as the coderlength \(n\) tends to infinity. It should be noted that Merhav and Neuhoff have also constructed a code achieving the optimum exponential decay rate [3]. However, their code is based on the enumerative code and is not practical from the viewpoint of complexity for encoding and decoding.
Proof of Theorem 2: For a sequence \( x_i \in \mathcal{X}^m, x \in \mathcal{X} \) and \( s \in \mathcal{S} \), let
\[
q(x, s) = \frac{1}{m} \sum_{i=1}^{m} \delta(x_i = x, s_{i-1} = s),
\]
where \( \delta(x_i = x, s_{i-1} = s) \) is the indicator function for \( x_i = x \) jointly with \( s_{i-1} = s \). Also, let
\[
q(x, s) = \sum_{x \in \mathcal{X}} q(x, x) \quad \text{and} \quad q(0, s) = q(x, s)/q(x, x);
\]
\( q(x, s) > 0 \) and \( q(0, s) = 0 \).

We denote by \( Q \) the empirical distribution
\[
Q \triangleq \{q(x, s) : x \in \mathcal{X}, s \in \mathcal{S}\}.
\]

Consider a sequence \( x \in \mathcal{X}^m \) of empirical distribution \( Q \). If \( x \) (and its following symbols) can be encoded into one codeword, the value of \( Y \) after reading \( x \) satisfies
\[
Y = \prod_{s \in Q} (M - 1)! \sum_{j=1}^{m} \frac{(mq(j, s)!)!}{(mq(j, s) + M - 1)!} \quad \text{for} \quad s \in \mathcal{S} \,
\]
\[
= \prod_{s \in Q} \left( \frac{(mq(s) + M - 1)^{-1} \prod_{j=1}^{m} (mq(j, s)!)!}{(mq(s)!)!} \frac{1}{M - 1} \right) \exp\{ -mH(Q) \}.
\]

Then, the probability that a sequence in \( \mathcal{X}^m \) is encoded into a sequence of more than \( mR \) bits can be upper bounded by
\[
\Pr\{x \in \mathcal{X}^m : \ell(f(x)) \geq mR\} \leq \sum_{Q \subseteq \mathcal{P}_m, \sum_{Q \subseteq \mathcal{P}_m} \exp\{-mD(Q \| P)\}} \leq (m + 1)^{M|Q|} \exp\left\{-\min_{Q \subseteq \mathcal{P}_m} mD(Q \| P)\right\}.
\]

where \( \mathcal{P}_m \) denotes the set of all empirical distributions for \( \mathcal{X}^m \), and the last inequality comes from \( |\mathcal{P}_m| \leq (m + 1)^{|\mathcal{X}|}\). By using (4), the condition
\[
H(Q) + \eta_m \geq R,
\]
where
\[
\eta_m \triangleq m^{-1} \{(M - 1)|Q| \log_2 (m + M - 1) + \log_2 (m + M + 1)\}.
\]

By choosing \( n = mR \) and combining (5) and (6), we obtain
\[
\frac{1}{n} \log_2 \Pr\{\ell(f(x)) > n\} = -\frac{1}{n} \log_2 \Pr\{x \in \mathcal{X}^{n/R} : \ell(f(x)) > n\}
\]
\[
\geq -\frac{M|Q| \log(n/R + 1)}{n} + \frac{1}{R} \min_{Q \subseteq \mathcal{P}_m} D(Q \| P),
\]
which implies (3).

\[ \square \]

Appendix: Construction of F-V length code from V-F length code

For the completeness, we describe a method introduced in [3].

1) Let \( T_n \) be a complete \( |\mathcal{X}| \)-ary tree corresponding to a given V-F length code with \( N(\leq 2^n) \) codewords. All words \( x_i \) with length \( \ell(x_i) \geq n/R \) can be shortened to \( |n/R| \), by pruning all subtrees with roots at depth \( |n/R| \). Then, we have a modified tree \( T_n' \) with all words no longer than \( |n/R| \), and with probability \( \Pr\{\ell(X) < n/R\} \) is equal to that of the original code \( T_n \).

2) Every word \( X \) with length \( \ell(X) < n/R \) is extended to \( |n/R| \) by all \( |\mathcal{X}|^{(n/R) - \ell(X)} \) possible suffixes, and accordingly, the \( n \)-bit codeword for this word is also extended by all possible \( (|n/R| - \ell(X)) \log |\mathcal{X}| \)-bit suffixes. Then, we have a F-V length code \( C_n \) with block length \( |n/R| \) and with length function \( \ell(X) \).

Note that the event \( \ell(X) < n/R \) for \( T_n \) is equivalent to the event \( \ell(X) > n \) for \( C_n \).
